1 General

1.1 Electric shock

An electric shock is the pathophysiological effect of an electric current through the human body. Its passage affects essentially the muscular, circulatory and respiratory functions and sometimes results in serious burns. The degree of danger for the victim is a function of the magnitude of the current, the parts of the body through which the current passes, and the duration of current flow.

IEC publication 60479-1 updated in 2005 defines four zones of current-magnitude/time-duration, in each of which the pathophysiological effects are described (see Fig F1). Any person coming into contact with live metal risks an electric shock.

Curve C1 shows that when a current greater than 30 mA passes through a human being from one hand to feet, the person concerned is likely to be killed, unless the current is interrupted in a relatively short time.

The protection of persons against electric shock in LV installations must be provided in conformity with appropriate national standards and statutory regulations, codes of practice, official guides and circulars etc. Relevant IEC standards include: IEC 60364, IEC 60479 series, IEC 61008, IEC 61009 and IEC 60947-2.
1.2 Protection against electric shock

The fundamental rule of protection against electric shock is provided by the document IEC 61140 which covers both electrical installations and electrical equipment.

Hazardous-live-parts shall not be accessible and accessible conductive parts shall not be hazardous.

This requirement needs to apply under:

- Normal conditions, and
- Under a single fault condition

Protection under normal condition corresponds to the protection against direct contact (basic protection) and the protection under single fault condition corresponds to the protection against indirect contact (fault protection).

Enhanced protective provisions provide protection under both conditions.

1.3 Direct and indirect contact

Direct contact
A direct contact refers to a person coming into contact with a conductor which is live in normal circumstances (see Fig. F2).

IEC 61140 standard has renamed “protection against direct contact” with the term “basic protection”. The former name is at least kept for information.

Indirect contact
An indirect contact refers to a person coming into contact with an exposed-conductive-part which is not normally alive, but has become alive accidentally (due to insulation failure or some other cause).

The fault current raise the exposed-conductive-part to a voltage liable to be hazardous which could be at the origin of a touch current through a person coming into contact with this exposed-conductive-part (see Fig. F3).

IEC 61140 standard has renamed “protection against indirect contact” with the term “fault protection”. The former name is at least kept for information.
Two complementary measures are commonly used as protection against the dangers of direct contact:

- The physical prevention of contact with live parts by barriers, insulation, inaccessibility, etc.
- Additional protection in the event that a direct contact occurs, despite or due to failure of the above measures. This protection is based on residual-current operating device with a high sensitivity (IΔn ≤ 30 mA) and a low operating time. These devices are highly effective in the majority of case of direct contact.

### 2.1 Measures of protection against direct contact

#### Protection by the insulation of live parts

This protection consists of an insulation which complies with the relevant standards (see Fig. F4). Paints, lacquers and varnishes do not provide an adequate protection.

![Fig. F4: Inherent protection against direct contact by insulation of a 3-phase cable with outer sheath](image)

#### Protection by means of barriers or enclosures

This measure is in widespread use, since many components and materials are installed in cabinets, assemblies, control panels and distribution boards (see Fig. F5).

To be considered as providing effective protection against direct contact hazards, these equipment must possess a degree of protection equal to at least IP 2X or IP XXB (see chapter E sub-clause 3.4).

Moreover, an opening in an enclosure (door, front panel, drawer, etc.) must only be removable, open or withdrawn:

- By means of a key or tool provided for this purpose, or
- After complete isolation of the live parts in the enclosure, or
- With the automatic interposition of another screen removable only with a key or a tool. The metal enclosure and all metal removable screen must be bonded to the protective earthing conductor of the installation.

#### Partial measures of protection

- Protection by means of obstacles, or by placing out of arm’s reach

This protection is reserved only to locations to which skilled or instructed persons only have access. The erection of this protective measure is detailed in IEC 60364-4-41.

#### Particular measures of protection

- Protection by use of extra-low voltage SELV (Safety Extra-Low Voltage) or by limitation of the energy of discharge.

These measures are used only in low-power circuits, and in particular circumstances, as described in section 3.5.
An additional measure of protection against the hazards of direct contact is provided by the use of residual current operating device, which operate at 30 mA or less, and are referred to as RCDs of high sensitivity.

2.2 Additional measure of protection against direct contact

All the preceding protective measures are preventive, but experience has shown that for various reasons they cannot be regarded as being infallible. Among these reasons may be cited:

- Lack of proper maintenance
- Imprudence, carelessness
- Normal (or abnormal) wear and tear of insulation; for instance flexure and abrasion of connecting leads
- Accidental contact
- Immersion in water, etc. A situation in which insulation is no longer effective

In order to protect users in such circumstances, highly sensitive fast tripping devices, based on the detection of residual currents to earth (which may or may not be through a human being or animal) are used to disconnect the power supply automatically, and with sufficient rapidity to prevent injury to, or death by electrocution, of a normally healthy human being (see Fig. F6).

These devices operate on the principle of differential current measurement, in which any difference between the current entering a circuit and that leaving it (on a system supplied from an earthed source) be flowing to earth, either through faulty insulation or through contact of an earthed part, such as a person, with a live conductor.

Standardised residual-current devices, referred to as RCDs, sufficiently sensitive for protection against direct contact are rated at 30 mA of differential current.

According to IEC 60364-4-41, additional protection by means of high sensitivity RCDs ($I_{\Delta n} < 30$ mA) must be provided for circuits supplying socket-outlets with a rated current $\leq 20$ A in all locations, and for circuits supplying mobile equipment with a rated current $\leq 32$ A for use outdoors.

This additional protection is required in certain countries for circuits supplying socket-outlets rated up to 32 A, and even higher if the location is wet and/or temporary (such as work sites for instance).

It is also recommended to limit the number of socket-outlets protected by a RCD (e.g. 10 socket-outlets for one RCD).

Chapter P section 3 itemises various common locations in which RCDs of high sensitivity are obligatory (in some countries), but in any case, are highly recommended as an effective protection against both direct and indirect contact hazards.
3 Protection against indirect contact

Exposed-conductive-parts used in the manufacturing process of an electrical equipment is separated from the live parts of the equipment by the "basic insulation". Failure of the basic insulation will result in the exposed-conductive-parts being alive. Touching a normally dead part of an electrical equipment which has become live due to the failure of its insulation, is referred to as an indirect contact.

Various measures are adopted to protect against this hazard, and include:
- Automatic disconnection of the power supply to the connected electrical equipment
- Special arrangements such as:
  - The use of class II insulation materials, or an equivalent level of insulation
  - Non-conducting location, out of arm’s reach or interposition of barriers
  - Equipotential bonding
  - Electrical separation by means of isolating transformers

3.1 Measures of protection by automatic disconnection of the supply

**Principle**

This protective measure depends on two fundamental requirements:
- The earthing of all exposed-conductive-parts of electrical equipment in the installation and the constitution of an equipotential bonding network
- Automatic disconnection of the supply of the section of the installation concerned, in such a way that the touch-voltage/time safety requirements are respected for any level of touch voltage $U_c$ (see Fig. F7)

**Reminder of the theoretical disconnecting-time limits**

(1) Touch voltage $U_c$ is the voltage existing (as the result of insulation failure) between an exposed-conductive-part and any conductive element within reach which is at a different (generally earth) potential.
3.2 Automatic disconnection for TT system

Principle
In this system all exposed-conductive-parts and extraneous-conductive-parts of the installation must be connected to a common earth electrode. The neutral point of the supply system is normally earthed at a point outside the influence area of the installation earth electrode, but need not be so. The impedance of the earth-fault loop therefore consists mainly in the two earth electrodes (i.e. the source and installation electrodes) in series, so that the magnitude of the earth fault current is generally too small to operate overcurrent relay or fuses, and the use of a residual current operated device is essential.

This principle of protection is also valid if one common earth electrode only is used, notably in the case of a consumer-type substation within the installation area, where space limitation may impose the adoption of a TN system earthing, but where all other conditions required by the TN system cannot be fulfilled.

Protection by automatic disconnection of the supply used in TT system is by RCD of sensitivity: 
\[ I_{an} \leq \frac{50}{R_A} \]

where 
- \( R_A \) is the resistance of the installation earth electrode
- \( I_{an} \) is the rated residual operating current of the RCD

For temporary supplies (to work sites, …) and agricultural and horticultural premises, the value of 50 V is replaced by 25 V.

Example (see Fig. F9)
- The resistance of the earth electrode of substation neutral \( R_n \) is 10 \( \Omega \).
- The resistance of the earth electrode of the installation \( R_A \) is 20 \( \Omega \).
- The earth-fault loop current \( I_f = 7.7 \text{ A} \).
- The fault voltage \( U_f = I_f \times R_A = 154 \text{ V} \) and therefore dangerous, but \( I_{an} = 50/20 = 2.5 \text{ A} \) so that a standard 300 mA RCD will operate in about 30 ms without intentional time delay and will clear the fault where a fault voltage exceeding appears on an exposed-conductive-part.

**Specified maximum disconnection time**

The tripping times of RCDs are generally lower than those required in the majority of national standards; this feature facilitates their use and allows the adoption of an effective discriminative protection.

The IEC 60364-4-41 specifies the maximum operating time of protective devices used in TT system for the protection against indirect contact:
- For all final circuits with a rated current not exceeding 32 A, the maximum disconnecting time will not exceed the values indicated in Figure F10.
- For all other circuits, the maximum disconnecting time is fixed to 1s. This limit enables discrimination between RCDs when installed on distribution circuits.
- RCD is a general term for all devices operating on the residual-current principle.
- RCCB (Residual Current Circuit-Breaker) as defined in IEC 61008 series is a specific class of RCD.
- Type G (general) and type S (Selective) of IEC 61008 have a tripping time/current characteristics as shown in Figure F11 next page. These characteristics allow a certain degree of selective tripping between the several combination of ratings and types, as shown later in sub-clause 4.3. Industrial type RCD according to IEC 60947-2 provide more possibilities of discrimination due to their flexibility of time-delaying.

(1) \( Uo \) is the nominal phase to earth voltage

**Fig. F10**: Maximum disconnecting time for AC final circuits not exceeding 32 A
Principle

In this system all exposed and extraneous-conductive-parts of the installation are connected directly to the earthed point of the power supply by protective conductors. As noted in Chapter E Sub-clause 1.2, the way in which this direct connection is carried out depends on whether the TN-C, TN-S, or TN-C-S method of implementing the TN principle is used. In figure F12 the method TN-C is shown, in which the neutral conductor acts as both the Protective-Earth and Neutral (PEN) conductor. In all TN systems, any insulation fault to earth results in a phase to neutral short-circuit. High fault current levels allow to use overcurrent protection but can give rise to touch voltages exceeding 50% of the phase to neutral voltage at the fault position during the short disconnection time.

In practice for utility distribution network, earth electrodes are normally installed at regular intervals along the protective conductor (PE or PEN) of the network, while the consumer is often required to install an earth electrode at the service entrance. On large installations additional earth electrodes dispersed around the premises are often provided, in order to reduce the touch voltage as much as possible. In high-rise apartment blocks, all extraneous conductive parts are connected to the protective conductor at each level. In order to ensure adequate protection, the earth-fault current must be higher or equal to the value required to operate the protective device in the time specified.

Note: The path through earth electrodes back to the source will have (generally) much higher impedance values than those listed above, and need not be considered.

Example (see Fig. F12)

The fault voltage \( U_f = \frac{230}{2} = 115 \text{ V} \) and is hazardous;

The fault loop impedance \( Z_s = Z_{AB} + Z_{BC} + Z_{DE} + Z_{EN} + Z_{NA} \).

If \( Z_{AC} \) and \( Z_{DE} \) are predominant, then:

\[
Z_s = 20 \angle Z_{AC} = 64.3 \text{ m} \Omega , \text{ so that}
\]

\[
I_d = \frac{230}{64.3 \times 10^{-3}} = 3.576 \text{ A} \approx 22 \text{ In} \text{ based on a NS 160 circuit-breaker}).
\]

The “instantaneous” magnetic trip unit adjustment of the circuit-breaker is many times less than this short-circuit value, so that positive operation in the shortest possible time is assured.

Note: Some authorities base such calculations on the assumption that a voltage drop of 20% occurs in the part of the impedance loop BANE.

This method, which is recommended, is explained in chapter F sub-clause 6.2 "conventional method" and in this example will give an estimated fault current of

\[
\frac{230 	imes 0.8 \times 10^{-3}}{64.3} = 2.816 \text{ A} \approx 18 \text{ In}.
\]
3 Protection against indirect contact

Specified maximum disconnection time
The IEC 60364-4-41 specifies the maximum operating time of protective devices used in TN system for the protection against indirect contact:

- For all final circuits with a rated current not exceeding 32 A, the maximum disconnecting time will not exceed the values indicated in Figure F13.
- For all other circuits, the maximum disconnecting time is fixed to 5s. This limit enables discrimination between protective devices installed on distribution circuits.

Note: The use of RCDs may be necessary on TN-earthed systems. Use of RCDs on TN-C-S systems means that the protective conductor and the neutral conductor must (evidently) be separated upstream of the RCD. This separation is commonly made at the service entrance.

(1) Uo is the nominal phase to earth voltage

Fig. F13: Maximum disconnection time for AC final circuits not exceeding 32 A

Protection by means of circuit-breaker (see Fig. F14)
The instantaneous trip unit of a circuit-breaker will eliminate a short-circuit to earth in less than 0.1 second.

In consequence, automatic disconnection within the maximum allowable time will always be assured, since all types of trip unit, magnetic or electronic, instantaneous or slightly retarded, are suitable: \( I_a = I_m \). The maximum tolerance authorised by the relevant standard, however, must always be taken into consideration. It is sufficient therefore that the fault current \( \frac{Uo}{Z_s} \) or \( 0.8 \frac{Uo}{Z_c} \) determined by calculation (or estimated on site) be greater than the instantaneous trip-setting current, or than the very short-time tripping threshold level, to be sure of tripping within the permitted time limit.

Protection by means of fuses (see Fig. F15)
The value of current which assures the correct operation of a fuse can be ascertained from a current/time performance graph for the fuse concerned.

The fault current \( \frac{Uo}{Z_s} \) or \( 0.8 \frac{Uo}{Z_c} \) as determined above, must largely exceed that necessary to ensure positive operation of the fuse. The condition to observe therefore is that \( I_a < \frac{Uo}{Z_s} \) or \( 0.8 \frac{Uo}{Z_c} \) as indicated in Figure F15.

If the protection is to be provided by a circuit-breaker, it is sufficient to verify that the fault current will always exceed the current-setting level of the instantaneous or short-time delay tripping unit (\( I_m \)).

\( I_a \) can be determined from the fuse performance curve. In any case, protection cannot be achieved if the loop impedance \( Z_s \) or \( Z_c \) exceeds a certain value.

Fig. F14: Disconnection by circuit-breaker for a TN system

Fig. F15: Disconnection by fuses for a TN system
3 Protection against indirect contact

Example: The nominal phase to neutral voltage of the network is 230 V and the maximum disconnection time given by the graph in Figure F15 is 0.4 s. The corresponding value of Iₐ can be read from the graph. Using the voltage (230 V) and the current Iₐ, the complete loop impedance or the circuit loop impedance can be calculated from 
\[ Z = \frac{230}{I_a} \] 
or 
\[ Z_c = 0.8 \times \frac{230}{I_a} \]. This impedance value must never be exceeded and should preferably be substantially less to ensure satisfactory fuse operation.

Protection by means of Residual Current Devices for TN-S circuits

Residual Current Devices must be used where:
- The loop impedance cannot be determined precisely (lengths difficult to estimate, presence of metallic material close to the wiring)
- The fault current is so low that the disconnecting time cannot be met by using overcurrent protective devices

The rated tripping current of RCDs being in the order of a few amps, it is well below the fault current level. RCDs are consequently well adapted to this situation. In practice, they are often installed in the LV sub distribution and in many countries, the automatic disconnection of final circuits shall be achieved by Residual Current Devices.

3.4 Automatic disconnection on a second fault in an IT system

In this type of system:
- The installation is isolated from earth, or the neutral point of its power-supply source is connected to earth through a high impedance
- All exposed and extraneous-conductive-parts are earthed via an installation earth electrode.

First fault situation

On the occurrence of a true fault to earth, referred to as a "first fault", the fault current is very low, such that the rule 
\[ I_d \times R_s \leq 50 \text{ V} \] (see F3.2) is fulfilled and no dangerous fault voltages can occur.

In practice the current Iₐ is low, a condition that is neither dangerous to personnel, nor harmful to the installation. However, in this system:
- A permanent monitoring of the insulation to earth must be provided, coupled with an alarm signal (audio and/or flashing lights, etc.) operating in the event of a first earth fault (see Fig. F16)
- The rapid location and repair of a first fault is imperative if the full benefits of the IT system are to be realised. Continuity of service is the great advantage afforded by the system.

For a network formed from 1 km of new conductors, the leakage (capacitive) impedance to earth Zf is of the order of 3,500 Ω per phase. In normal operation, the capacitive current(1) to earth is therefore:

\[ U_0 = \frac{230}{Z_f} = 66 \text{ mA per phase.} \]

During a phase to earth fault, as indicated in Figure F17 opposite page, the current passing through the electrode resistance RnA is the vector sum of the capacitive currents in the two healthy phases. The voltages of the healthy phases have (because of the fault) increased to \( \sqrt{3} \) the normal phase voltage, so that the capacitive currents increase by the same amount. These currents are displaced, one from the other by 60°, so that when added vectorially, this amounts to 3 x 66 mA = 198 mA, in the present example.

The fault voltage Uf is therefore equal to 198 x 5 x 10⁻³ = 0.99 V, which is obviously harmless.

The current through the short-circuit to earth is given by the vector sum of the neutral-resistor current Iₐ1 (=153 mA) and the capacitive current Iₐ2 (198 mA).

Since the exposed-conductive-parts of the installation are connected directly to earth, the neutral impedance Zcₐ plays practically no part in the production of touch voltages to earth.

---

In IT system the first fault to earth should not cause any disconnection

Fig. F16 : Phases to earth insulation monitoring device obligatory in IT system

(1) Resistive leakage current to earth through the insulation is assumed to be negligibly small in the example.
Second fault situation

On the appearance of a second fault, on a different phase, or on a neutral conductor, a rapid disconnection becomes imperative. Fault clearance is carried out differently in each of the following cases:

1st case

It concerns an installation in which all exposed conductive parts are bonded to a common PE conductor, as shown in Figure F18.

In this case no earth electrodes are included in the fault current path, so that a high level of fault current is assured, and conventional overcurrent protective devices are used, i.e. circuit-breakers and fuses.

The first fault could occur at the end of a circuit in a remote part of the installation, while the second fault could feasibly be located at the opposite end of the installation.

For this reason, it is conventional to double the loop impedance of a circuit, when calculating the anticipated fault setting level for its overcurrent protective device(s).

Where the system includes a neutral conductor in addition to the 3 phase conductors, the lowest short-circuit fault currents will occur if one of the (two) faults is from the neutral conductor to earth (all four conductors are insulated from earth in an IT scheme). In four-wire IT installations, therefore, the phase-to-neutral voltage must be used to calculate short-circuit protective levels i.e.

\[ 0.8 \frac{U_o}{2Z_c} \times I_a(1) \]

where

- \( U_o \) = phase to neutral voltage
- \( Z_c \) = impedance of the circuit fault-current loop (see F3.3)
- \( I_a \) = current level for trip setting

If no neutral conductor is distributed, then the voltage to use for the fault-current calculation is the phase-to-phase value, i.e.

\[ 0.8 \frac{3U_o}{2Z_c} \times I_a(1) \]

Maximum tripping times

Disconnecting times for IT system depends on how the different installation and substation earth electrodes are interconnected.

For final circuits supplying electrical equipment with a rated current not exceeding 32 A and having their exposed-conductive-parts bonded with the substation earth electrode, the maximum tripping time is given in table F8. For the other circuits within the same group of interconnected exposed-conductive-parts, the maximum disconnecting time is 5 s. This is due to the fact that any double fault situation within this group will result in a short-circuit current as in TN system.

For final circuits supplying electrical equipment with a rated current not exceeding 32 A and having their exposed-conductive-parts connected to an independent earth electrode electrically separated from the substation earth electrode, the maximum tripping time is given in Figure F13. For the other circuits within the same group of non interconnected exposed-conductive-parts, the maximum disconnecting time is 1 s. This is due to the fact that any double fault situation resulting from one insulation fault within this group and another insulation fault from another group will generate a fault current limited by the different earth electrode resistances as in TT system.

---

The simultaneous existence of two earth faults (if not both on the same phase) is dangerous, and rapid clearance by fuses or automatic circuit-breaker tripping depends on the type of earth-bonding scheme, and whether separate earthing electrodes are used or not, in the installation concerned.

---

(1) Based on the "conventional method" noted in the first example of Sub-clause 3.3.
Protection against indirect contact

Protection by circuit-breaker

In the case shown in Figure F18, the adjustments of instantaneous and short-time delay overcurrent trip unit must be decided. The times recommended here above can be readily complied with. The short-circuit protection provided by the NS 160 circuit-breaker is suitable to clear a phase to phase short-circuit occurring at the load ends of the circuits concerned.

Reminder: In an IT system, the two circuits involved in a phase to phase short-circuit are assumed to be of equal length, with the same cross sectional area conductors, the PE conductors being the same cross sectional area as the phase conductors. In such a case, the impedance of the circuit loop when using the "conventional method" (sub clause 6.2) will be twice that calculated for one of the circuits in the TN case, shown in Chapter F sub clause 3.3.

The resistance of circuit loop FGHJ = \( 2R_{JH} = 2 \cdot 22.5 \times 50/35 = 64.3 \) m\(\Omega\).

and the loop resistance B, C, D, E, F, G, H, J will be 2 x 64.3 = 129 m\(\Omega\).

The fault current will therefore be 0.8 x 129 x 230 x 10^3/129 = 2,470 A.

Protection by fuses

The current \(I_a\) for which fuse operation must be assured in a time specified according to here above can be found from fuse operating curves, as described in figure F15. The current indicated should be significantly lower than the fault currents calculated for the circuit concerned.

Protection by Residual current circuit-breakers (RCCBs)

For low values of short-circuit current, RCCBs are necessary. Protection against indirect contact hazards can be achieved then by using one RCCB for each circuit.

2nd case

It concerns exposed conductive parts which are earthed either individually (each part having its own earth electrode) or in separate groups (one electrode for each group).

If all exposed conductive parts are not bonded to a common electrode system, then it is possible for the second earth fault to occur in a different group or in a separately earthed individual apparatus. Additional protection to that described above for case 1, is required, and consists of a RCD placed at the circuit-breaker controlling each group and each individually-earthed apparatus.
F - Protection against electric shock

3 Protection against indirect contact

The reason for this requirement is that the separate-group electrodes are “bonded” through the earth so that the phase to phase short-circuit current will generally be limited when passing through the earth bond by the electrode contact resistances with the earth, thereby making protection by overcurrent devices unreliable. The more sensitive RCDs are therefore necessary, but the operating current of the RCDs must evidently exceed that which occurs for a first fault (see Fig. F19).

Note: 1 µF is the 1 km typical leakage capacitance for 4-conductor cable.

Fig. F19: Correspondence between the earth leakage capacitance and the first fault current

For a second fault occurring within a group having a common earth-electrode system, the overcurrent protection operates, as described above for case 1.

Note 1: See also Chapter G Sub-clause 7.2, protection of the neutral conductor.

Note 2: In 3-phase 4-wire installations, protection against overcurrent in the neutral conductor is sometimes more conveniently achieved by using a ring-type current transformer over the single-core neutral conductor (see Fig. F20).

Fig. F20: Application of RCDs when exposed-conductive-parts are earthed individually or by group on IT system

3.5 Measures of protection against direct or indirect contact without automatic disconnection of supply

The use of SELV (Safety Extra-Low Voltage)

Safety by extra low voltage SELV is used in situations where the operation of electrical equipment presents a serious hazard (swimming pools, amusement parks, etc.). This measure depends on supplying power at extra-low voltage from the secondary windings of isolating transformers especially designed according to national or to international (IEC 60742) standard. The impulse withstand level of insulation between the primary and secondary windings is very high, and/or an earthed metal screen is sometimes incorporated between the windings. The secondary voltage never exceeds 50 V rms.

Three conditions of exploitation must be respected in order to provide satisfactory protection against indirect contact:

- No live conductor at SELV must be connected to earth
- Exposed-conductive-parts of SELV supplied equipment must not be connected to earth, to other exposed conductive parts, or to extraneous-conductive-parts
- All live parts of SELV circuits and of other circuits of higher voltage must be separated by a distance at least equal to that between the primary and secondary windings of a safety isolating transformer.

Extra-low voltage is used where the risks are great: swimming pools, wandering-hand lamps, and other portable appliances for outdoor use, etc.
These measures require that:
- SELV circuits must use conduits exclusively provided for them, unless cables which are insulated for the highest voltage of the other circuits are used for the SELV circuits.
- Socket outlets for the SELV system must not have an earth-pin contact. The SELV circuit plugs and sockets must be special, so that inadvertent connection to a different voltage level is not possible.

**Note:** In normal conditions, when the SELV voltage is less than 25 V, there is no need to provide protection against direct contact hazards. Particular requirements are indicated in Chapter P, Clause 3: “special locations”.

**The use of PELV (Protection by Extra Low Voltage) (see Fig. F21)**

This system is for general use where low voltage is required, or preferred for safety reasons, other than in the high-risk locations noted above. The conception is similar to that of the SELV system, but the secondary circuit is earthed at one point.

IEC 60364-4-41 defines precisely the significance of the reference PELV. Protection against direct contact hazards is generally necessary, except when the equipment is in the zone of equipotential bonding, and the nominal voltage does not exceed 25 V rms, and the equipment is used in normally dry locations only, and large-area contact with the human body is not expected. In all other cases, 6 V rms is the maximum permitted voltage, where no direct contact protection is provided.

**FELV system (Functional Extra-Low Voltage)**

Where, for functional reasons, a voltage of 50 V or less is used, but not all of the requirements relating to SELV or PELV are fulfilled, appropriate measures described in IEC 60364-4-41 must be taken to ensure protection against both direct and indirect contact hazards, according to the location and use of these circuits.

**Note:** Such conditions may, for example, be encountered when the circuit contains equipment (such as transformers, relays, remote-control switches, contactors) insufficiently insulated with respect to circuits at higher voltages.

**The electrical separation of circuits (see Fig. F22)**

The principle of the electrical separation of circuits (generally single-phase circuits) for safety purposes is based on the following rationale.

The two conductors from the unearthed single-phase secondary winding of a separation transformer are insulated from earth.

If a direct contact is made with one conductor, a very small current only will flow into the person making contact, through the earth and back to the other conductor, via the inherent capacitance of that conductor with respect to earth. Since the conductor capacitance to earth is very small, the current is generally below the level of perception.

As the length of circuit cable increases, the direct contact current will progressively increase to a point where a dangerous electric shock will be experienced.

Even if a short length of cable precludes any danger from capacitive current, a low value of insulation resistance with respect to earth can result in danger, since the current path is then via the person making contact, through the earth and back to the other conductor through the low conductor-to-earth insulation resistance.

For these reasons, relatively short lengths of well insulated cables are essential in separation systems.

Transformers are specially designed for this duty, with a high degree of insulation between primary and secondary windings, or with equivalent protection, such as an earthed metal screen between the windings. Construction of the transformer is to class II insulation standards.
3 Protection against indirect contact

As indicated before, successful exploitation of the principle requires that:
- No conductor or exposed conductive part of the secondary circuit must be connected to earth,
- The length of secondary cabling must be limited to avoid large capacitance values\(^1\),
- A high insulation-resistance value must be maintained for the cabling and appliances.

These conditions generally limit the application of this safety measure to an individual appliance.

In the case where several appliances are supplied from a separation transformer, it is necessary to observe the following requirements:
- The exposed conductive parts of all appliances must be connected together by an insulated protective conductor, but not connected to earth,
- The socket outlets must be provided with an earth-pin connection. The earth-pin connection is used in this case only to ensure the interconnection (bonding) of all exposed conductive parts.

In the case of a second fault, overcurrent protection must provide automatic disconnection in the same conditions as those required for an IT system of power system earthing.

Class II equipment

These appliances are also referred to as having “double insulation” since in class II appliances a supplementary insulation is added to the basic insulation (see Fig. F23).

No conductive parts of a class II appliance must be connected to a protective conductor:
- Most portable or semi-fixed equipment, certain lamps, and some types of transformer are designed to have double insulation. It is important to take particular care in the exploitation of class II equipment and to verify regularly and often that the class II standard is maintained (no broken outer envelope, etc.). Electronic devices, radio and television sets have safety levels equivalent to class II, but are not formally class II appliances
- Supplementary insulation in an electrical installation: IEC 60364-4-41(Sub-clause 413-2) and some national standards such as NF C 15-100 (France) describe in more detail the necessary measures to achieve the supplementary insulation during installation work.

A simple example is that of drawing a cable into a PVC conduit. Methods are also described for distribution boards.
- For distribution boards and similar equipment, IEC 60439-1 describes a set of requirements, for what is referred to as “total insulation”, equivalent to class II
- Some cables are recognised as being equivalent to class II by many national standards

Out-of-arm’s reach or interposition of obstacles

By these means, the probability of touching a live exposed-conductive-part, while at the same time touching an extraneous-conductive-part at earth potential, is extremely low (see Fig. F24 next page). In practice, this measure can only be applied in a dry location, and is implemented according to the following conditions:
- The floor and the wall of the chamber must be non-conducting, i.e. the resistance to earth at any point must be:
  - \(> 50 \, \text{k}\Omega\) (installation voltage \(\leq 500\,\text{V}\))
  - \(> 100 \, \text{k}\Omega\) (500 V < installation voltage \(\leq 1000\,\text{V}\))

Resistance is measured by means of “MEGGER” type instruments (hand-operated generator or battery-operated electronic model) between an electrode placed on the floor or against the wall, and earth (i.e. the nearest protective earth conductor). The electrode contact area pressure must be evidently the same for all tests.

Different instruments suppliers provide electrodes specific to their own product, so that care should be taken to ensure that the electrodes used are those supplied with the instrument.

\(^1\) It is recommended in IEC 364-4-41 that the product of the nominal voltage of the circuit in volts and length in metres of the wiring system should not exceed 100,000, and that the length of the wiring system should not exceed 500 m.
F - Protection against electric shock

F1

Earth-free equipotential chambers

In this scheme, all exposed-conductive-parts, including the floor, are bonded by suitably large conductors, such that no significant difference of potential can exist between any two points. A failure of insulation between a live conductor and the metal envelope of an appliance will result in the whole “cage” being raised to phase-to-earth voltage, but no fault current will flow. In such conditions, a person entering the chamber would be at risk (since he/she would be stepping on a live floor). Suitable precautions must be taken to protect personnel from this danger (e.g. non-conducting floor at entrances, etc.). Special protective devices are also necessary to detect insulation failure, in the absence of significant fault current.

(1) Extraneous conductive parts entering (or leaving) the equipotential space (such as water pipes, etc.) must be encased in suitable insulating material and excluded from the equipotential network, since such parts are likely to be bonded to protective (earthed) conductors elsewhere in the installation.

Fig. F24 : Protection by out-of-arm’s reach arrangements and the interposition of non-conducting obstacles

Fig. F25 : Equipotential bonding of all exposed-conductive-parts simultaneously accessible
4 Protection of goods in case of insulation fault

The standards consider the damage (mainly fire) of goods due to insulation faults to be high. Therefore, for location with high risk of fire, 300 mA Residual Current Devices must be used. For the other locations, some standards relies on technique called « Ground Fault Protection » (GFP).

4.1 Measures of protection against fire risk with RCDs

RCDs are very effective devices to provide protection against fire risk due to insulation fault. This type of fault current is actually too low to be detected by the other protection (overcurrent, reverse time).

For TT, IT TN-S systems in which leakage current can appear, the use of 300 mA sensitivity RCDs provides a good protection against fire risk due to this type of fault.

An investigation has shown that the cost of the fires in industrial and tertiary buildings can be very great.

The analysis of the phenomena shows that fire risk due to electricity is linked to overheating due to a bad coordination between the maximum rated current of the cable (or isolated conductor) and the overcurrent protection setting.

Overheating can also be due to the modification of the initial method of installation (addition of cables on the same support).

This overheating can be the origin of electrical arc in humid environment. These electrical arcs evolve when the fault current-loop impedance is greater than 0.6 Ω and exist only when an insulation fault occurs. Some tests have shown that a 300 mA fault current can induce a real risk of fire (see Fig. F26).

4.2 Ground Fault Protection (GFP)

Different type of ground fault protections (see Fig. F27)

Three types of GFP are possible dependind on the measuring device installed :

- “Residual Sensing” RS
  The "insulation fault" current is calculated using the vectorial sum of currents of current transformers secondaries. The current transformer on the neutral conductor is often outside the circuit-breaker.

- “Source Ground Return” SGR
  The "insulation fault current" is measured in the neutral – earth link of the LV transformer. The current transformer is outside the circuit-breaker.

- “Zero Sequence” ZS
  The "insulation fault" is directly measured at the secondary of the current transformer using the sum of currents in live conductors. This type of GFP is only used with low fault current values.

5 Implementation of the TT system

5.1 Protective measures

Protection against indirect contact

General case

Protection against indirect contact is assured by RCDs, the sensitivity $I_{\Delta n}$ of which complies with the condition $I_{\Delta n} \leq \frac{50 \text{ V}}{R_A} \text{(1)}$

The choice of sensitivity of the residual current device is a function of the resistance $R_A$ of the earth electrode for the installation, and is given in Figure F28.

Fig. F28: The upper limit of resistance for an installation earthing electrode which must not be exceeded, for given sensitivity levels of RCDs at $U_L$ voltage limits of 50 V and 25 V.

Case of distribution circuits (see Fig. F29)

IEC 60364-4-41 and a number of national standards recognize a maximum tripping time of 1 second in installation distribution circuits (as opposed to final circuits). This allows a degree of selective discrimination to be achieved:

- At level A: RCD time-delayed, e.g. "S" type
- At level B: RCD instantaneous

Case where the exposed conductive parts of an appliance, or group of appliances, are connected to a separate earth electrode (see Fig. F30)

Protection against indirect contact by a RCD at the circuit-breaker level protecting each group or separately-earthed individual appliance.

In each case, the sensitivity must be compatible with the resistance of the earth electrode concerned.

High-sensitivity RCDs (see Fig. F31)

According to IEC 60364-4-41, high sensitivity RCDs (< 30 mA) must be used for protection of socket outlets with rated current < 20 A in all locations. The use of such RCDs is also recommended in the following cases:

- Socket-outlet circuits in wet locations at all current ratings
- Socket-outlet circuits in temporary installations
- Circuits supplying laundry rooms and swimming pools
- Supply circuits to work-sites, caravans, pleasure boats, and travelling fairs

See 2.2 and chapter P, section 3

Fig. F29: Distribution circuits

Fig. F30: Separate earth electrode

Fig. F31: Circuit supplying socket-outlets

(1) 25 V for work-site installations, agricultural establishments, etc.
In high fire risk locations (see Fig. F32)
RCD protection at the circuit-breaker controlling all supplies to the area at risk is necessary in some locations, and mandatory in many countries.
The sensitivity of the RCD must be ≤ 500 mA, but a 300 mA sensitivity is recommended.

Protection when exposed conductive parts are not connected to earth (see Fig. F33)
(In the case of an existing installation where the location is dry and provision of an earthing connection is not possible, or in the event that a protective earth wire becomes broken).
RCDs of high sensitivity (≤ 30 mA) will afford both protection against indirect-contact hazards, and the additional protection against the dangers of direct-contact.

5.2 Types of RCDs
Residual current devices (RCD) are commonly incorporated in or associated with the following components:
- Industrial-type moulded-case circuit-breakers (MCCB) conforming to IEC 60947-2 and its appendix B and M
- Industrial type miniature circuit-breakers (MCB) conforming to IEC 60947-2 and its appendix B and M
- Household and similar miniature circuit-breakers (MCB) complying with IEC 60898, IEC 61008, IEC 61009
- Residual load switch conforming to particular national standards
- Relays with separate toroidal (ring-type) current transformers, conforming to IEC 60947-2 Appendix M
RCDs are mandatorily used at the origin of TT-earthed installations, where their ability to discriminate with other RCDs allows selective tripping, thereby ensuring the level of service continuity required.

Industrial type circuit-breakers with integrated or adaptable RCD module (see Fig. F34)

Industrial type circuit-breaker
Vigi Compact

Multi 9 DIN-rail industrial
Circuit-breaker with adaptable Vigi RCD module

Adaptable residual current circuit-breakers, including DIN-rail mounted units (e.g. Compact or Multi 9), are available, to which may be associated an auxiliary RCD module (e.g. Vigi).

The ensemble provides a comprehensive range of protective functions (isolation, protection against short-circuit, overload, and earth-fault.

Household and similar miniature circuit-breakers with RCD (see Fig. F35)

The incoming-supply circuit-breaker can also have time-delayed characteristics and integrate a RCD (type S).

“Monobloc” Déclic Vigi residual current circuit-breakers intended for protection of terminal socket-outlet circuits in domestic and tertiary sector applications.
Discriminative-tripping coordination is achieved either by time-delay or by subdivision of circuits, which are then protected individually or by groups, or by a combination of both methods.

Such discrimination avoids the tripping of any RCD, other than that immediately upstream of a fault position:

- With equipment currently available, discrimination is possible at three or four different levels of distribution:
  - At the main general distribution board
  - At local general distribution boards
  - At sub-distribution boards
  - At socket outlets for individual appliance protection
- In general, at distribution boards (and sub-distribution boards, if existing) and on individual-appliance protection, devices for automatic disconnection in the event of an indirect-contact hazard occurring are installed together with additional protection against direct-contact hazards.

**Discrimination between RCDs**

The general specification for achieving total discrimination between two RCDs is as follow:

- The ratio between the rated residual operating currents must be $> 2$
- Time delaying the upstream RCD

Discrimination is achieved by exploiting the several levels of standardized sensitivity: 30 mA, 100 mA, 300 mA and 1 A and the corresponding tripping times, as shown opposite page in [Figure F38](#).
5 Implementation of the TT system

Discrimination at 2 levels (see Fig. F39)

Protection
- Level A: RCD time-delayed setting I (for industrial device) or type S (for domestic device) for protection against indirect contacts
- Level B: RCD instantaneous, with high sensitivity on circuits supplying socket-outlets or appliances at high risk (washing machines, etc.) See also Chapter P Clause 3

Schneider Electric solutions
- Level A: Compact or Multi 9 circuit-breaker with adaptable RCD module (Vigi NS160 or Vigi NC100), setting I or S type
- Level B: Circuit-breaker with integrated RCD module (DPN Vigi) or adaptable RCD module (e.g. Vigi C60 or Vigi NC100) or Vigicompact

Note: The setting of upstream RCCB must comply with selectivity rules and take into account all the downstream earth leakage currents.

Discrimination at 3 or 4 levels (see Fig. F40)

Protection
- Level A: RCD time-delayed (setting III)
- Level B: RCD time-delayed (setting II)
- Level C: RCD time-delayed (setting I) or type S
- Level D: RCD instantaneous

Schneider Electric solutions
- Level A: Circuit-breaker associated with RCD and separate toroidal transformer (Vigirex RH54A)
- Level B: Vigicompact or Vigirex
- Level C: Vigirex, Vigicompact or Vigi NC100 or Vigi C60
- Level D:
  - Vigicompact or
  - Vigirex or
  - Multi 9 with integrated or adaptable RCD module : Vigi C60 or DPN Vigi

Note: The setting of upstream RCCB must comply with selectivity rules and take into account all the downstream earth leakage currents
Discriminative protection at three levels (see Fig. F41)

Fig. F41: Typical 3-level installation, showing the protection of distribution circuits in a TT-earthed system. One motor is provided with specific protection.
6. Implementation of the TN system

6.1 Preliminary conditions

At the design stage, the maximum permitted lengths of cable downstream of a protective circuit-breaker (or set of fuses) must be calculated, while during the installation work certain rules must be fully respected.

Certain conditions must be observed, as listed below and illustrated in Figure F42.

1. PE conductor must be regularly connected to earth as much as possible.
2. The PE conductor must not pass through ferro-magnetic conduit, ducts, etc. or be mounted on steel work, since inductive and/or proximity effects can increase the effective impedance of the conductor.
3. In the case of a PEN conductor (a neutral conductor which is also used as a protective conductor), connection must be made directly to the earth terminal of an appliance (see 3 in Figure F42) before being looped to the neutral terminal of the same appliance.
4. Where the conductor ≤ 6 mm² for copper or 10 mm² for aluminium, or where a cable is movable, the neutral and protective conductors should be separated (i.e. a TN-S system should be adopted within the installation).
5. Earth faults may be cleared by overcurrent-protection devices, i.e. by fuses and circuit-breakers.

The foregoing list indicates the conditions to be respected in the implementation of a TN scheme for the protection against indirect contacts.

---

**Figure F42**: Implementation of the TN system of earthing

Notes:
- The TN scheme requires that the LV neutral of the MV/LV transformer, the exposed conductive parts of the substation and of the installation, and the extraneous conductive parts in the substation and installation, all be earthed to a common earthing system.
- For a substation in which the metering is at low-voltage, a means of isolation is required at the origin of the LV installation, and the isolation must be clearly visible.
- A PEN conductor must never be interrupted under any circumstances. Control and protective switchgear for the several TN arrangements will be:
  - 3-pole when the circuit includes a PEN conductor,
  - Preferably 4-pole (3 phases + neutral) when the circuit includes a neutral with a separate PE conductor.

---

6.2 Protection against indirect contact

Methods of determining levels of short-circuit current

In TN-earthed systems, a short-circuit to earth will, in principle, always provide sufficient current to operate an overcurrent device.

The source and supply mains impedances are much lower than those of the installation circuits, so that any restriction in the magnitude of earth-fault currents will be mainly caused by the installation conductors (long flexible leads to appliances greatly increase the “fault-loop” impedance, with a corresponding reduction of short-circuit current).

The most recent IEC recommendations for indirect-contact protection on TN earthing systems only relates maximum allowable tripping times to the nominal system voltage (see Figure F12 in Sub-clause 3.3).
The reasoning behind these recommendations is that, for TN systems, the current which must flow in order to raise the potential of an exposed conductive part to 50 V or more is so high that one of two possibilities will occur:

- Either the fault path will blow itself clear, practically instantaneously, or
- The conductor will weld itself into a solid fault and provide adequate current to operate overcurrent devices

To ensure correct operation of overcurrent devices in the latter case, a reasonably accurate assessment of short-circuit earth-fault current levels must be determined at the design stage of a project.

A rigorous analysis requires the use of phase-sequence-component techniques applied to every circuit in turn. The principle is straightforward, but the amount of computation is not considered justifiable, especially since the zero-phase-sequence impedances are extremely difficult to determine with any reasonable degree of accuracy in an average LV installation.

Other simpler methods of adequate accuracy are preferred. Three practical methods are:

- The “method of impedances”, based on the summation of all the impedances (positive-phase-sequence only) around the fault loop, for each circuit
- The “method of composition”, which is an estimation of short-circuit current at the remote end of a loop, when the short-circuit current level at the near end of the loop is known
- The “conventional method” of calculating the minimum levels of earth-fault currents, together with the use of tables of values for obtaining rapid results

These methods are only reliable for the case in which the cables that make up the earth-fault-current loop are in close proximity (to each other) and not separated by ferro-magnetic materials.

**Method of impedances**

This method sums the positive-sequence impedances of each item (cable, PE conductor, transformer, etc.) included in the earth-fault loop circuit from which the short-circuit earth-fault current is calculated, using the formula:

\[ I = \frac{U}{\sqrt{\left(\sum R\right)^2 + \left(\sum X\right)^2}} \]

where

- \( \left(\sum R\right)^2 = \text{the sum of all resistances in the loop}^2 \) at the design stage of a project.
- \( \left(\sum X\right)^2 = \text{the sum of all inductive reactances in the loop}^2 \)
- \( U = \text{nominal system phase-to-neutral voltage} \)

The application of the method is not always easy, because it supposes a knowledge of all parameter values and characteristics of the elements in the loop. In many cases, a national guide can supply typical values for estimation purposes.

**Method of composition**

This method permits the determination of the short-circuit current at the end of a loop from the known value of short-circuit at the sending end, by means of the approximate formula:

\[ I = \frac{I_{sc}}{U + Z_s I_{sc}} \]

where

- \( I_{sc} = \text{upstream short-circuit current} \)
- \( I = \text{end-of-loop short-circuit current} \)
- \( U = \text{nominal system phase voltage} \)
- \( Z_s = \text{impedance of loop} \)

**Note:** In this method the individual impedances are added arithmetically\(^{(1)}\) as opposed to the previous “method of impedances” procedure.

**Conventional method**

This method is generally considered to be sufficiently accurate to fix the upper limit of cable lengths.

**Principle**

The principle bases the short-circuit current calculation on the assumption that the voltage at the origin of the circuit concerned (i.e. at the point at which the circuit protective device is located) remains at 80% or more of the nominal phase to neutral voltage. The 80% value is used, together with the circuit loop impedance, to compute the short-circuit current.

\(^{(1)}\) This results in a calculated current value which is less than that it would actually flow. If the overcurrent settings are based on this calculated value, then operation of the relay, or fuse, is assured.
6 Implementation of the TN system

This coefficient takes account of all voltage drops upstream of the point considered. In LV cables, when all conductors of a 3-phase 4-wire circuit are in close proximity (which is the normal case), the inductive reactance internal to and between conductors is negligibly small compared to the cable resistance.

This approximation is considered to be valid for cable sizes up to 120 mm².

Above that size, the resistance value $R$ is increased as follows:

$$L_{max} = \frac{0.8 \, U_o \, \rho(1+m)}{I_a}$$

The maximum length of any circuit of a TN-earthed installation is:

$$L_{max} = \frac{0.8 \, U_o \, S_{ph}}{\rho(1+m)}$$

where:

- $L_{max}$ = maximum length in metres
- $U_o$ = phase volts = 230 V for a 230/400 V system
- $\rho$ = resistivity at normal working temperature in ohm-mm²/metre ($= 22.5 \times 10^{-3}$ for copper; $= 36 \times 10^{-3}$ for aluminium)
- $I_a$ = trip current setting for the instantaneous operation of a circuit-breaker, or $I_{a_m}$ = the current which assures operation of the protective fuse concerned, in the specified time.
- $m = \frac{S_{ph}}{S_{PE}}$

$S_{ph} =$ cross-sectional area of the phase conductors of the circuit concerned in mm²

$S_{PE} =$ cross-sectional area of the protective conductor concerned in mm².

### Tables

The following tables, applicable to TN systems, have been established according to the "conventional method" described above.

The tables give maximum circuit lengths, beyond which the ohmic resistance of the conductors will limit the magnitude of the short-circuit current to a level below that required to trip the circuit-breaker (or to blow the fuse) protecting the circuit, with sufficient rapidity to ensure safety against indirect contact.

**Correction factor $m$**

Figure F44 indicates the correction factor to apply to the values given in Figures F45 to F48 next pages, according to the ratio $S_{ph}/S_{PE}$, the type of circuit, and the conductor materials.

The tables take into account:

- The type of protection: circuit-breakers or fuses
- Operating-current settings
- Cross-sectional area of phase conductors and protective conductors
- Type of system earthing (see Fig. F49 page F29)
- Type of circuit-breaker (i.e. B, C or D)(1)

The tables may be used for 230/400 V systems.

Equivalent tables for protection by Compact and Multi 9 circuit-breakers (Merlin Gerin) are included in the relevant catalogues.

### The maximum length of any circuit of a TN-earthed installation is:

$$L_{max} = \frac{0.8 \, U_o \, S_{ph}}{\rho(1+m)}$$

### The following tables give the length of circuit which must not be exceeded, in order that persons be protected against indirect contact hazards by protective devices

**Fig. F43**: Calculation of $L_{max}$ for a TN-earthed system, using the conventional method

**Fig. F44**: Correction factor to apply to the lengths given in tables F44 to F47 for TN systems

---

Fig. F47: Maximum circuit lengths (in metres) for different sizes of copper conductor and rated currents for type C\(^{(2)}\) circuit-breakers in a 230/240 V single-phase or three-phase TN system with $m = 1$

(1) Merlin Gerin products.
(2) For the definition of type B and C circuit-breakers refer to chapter H clause 4.2.
6 Implementation of the TN system

Example

A 3-phase 4-wire (230/400 V) installation is TN-C earthed. A circuit is protected by a type B circuit-breaker rated at 63 A, and consists of an aluminium cored cable with 50 mm² phase conductors and a neutral conductor (PEN) of 25 mm².

What is the maximum length of circuit, below which protection of persons against indirect-contact hazards is assured by the instantaneous magnetic tripping relay of the circuit-breaker?

Figure F46 gives, for 50 mm² and a 63 A type B circuit-breaker, 603 metres, to which must be applied a factor of 0.42 (Figure F44 for $S_p E = 2$).

The maximum length of circuit is therefore:

$$603 \times 0.42 = 253 \text{ metres}.$$ 

Particular case where one or more exposed conductive part(s) is (are) earthed to a separate earth electrode

Protection must be provided against indirect contact by a RCD at the origin of any circuit supplying an appliance or group of appliances, the exposed conductive parts of which are connected to an independent earth electrode.

The sensitivity of the RCD must be adapted to the earth electrode resistance ($R_{A2}$ in Figure F49). See specifications applicable to TT system.

6.3 High-sensitivity RCDs (see Fig. F31)

According to IEC 60364-4-41, high sensitivity RCDs ($\leq 30 \text{ mA}$) must be used for protection of socket outlets with rated current $< 20 \text{ A}$ in all locations. The use of such RCDs is also recommended in the following cases:

- Socket-outlet circuits in wet locations at all current ratings
- Socket-outlet circuits in temporary installations
- Circuits supplying laundry rooms and swimming pools
- Supply circuits to work-sites, caravans, pleasure boats, and travelling fairs

See 2.2 and chapter P, al section 3.

Fig. F49: Separate earth electrode

Fig. F50: Circuit supplying socket-outlets

(1) For the definition of type D circuit-breaker refer to chapter H Sub-clause 4.2.
6.4 Protection in high fire-risk location

According to IEC 60364-4-22-3.10, circuits in high fire-risk locations must be protected by RCDs of sensitivity < 500 mA. This excludes the TN-C arrangement and TN-S must be adopted.

A preferred sensitivity of 300 mA is mandatory in some countries (see Fig. F51).

6.5 When the fault current-loop impedance is particularly high

When the earth-fault current is limited due to an inevitably high fault-loop impedance, so that the overcurrent protection cannot be relied upon to trip the circuit within the prescribed time, the following possibilities should be considered:

**Suggestion 1** (see Fig. F52)
- Install a circuit-breaker which has a lower instantaneous magnetic tripping level, for example:
  \[ 2I_n \leq I_{\text{rm}} \leq 4I_n \]
  This affords protection for persons on circuits which are abnormally long. It must be checked, however, that high transient currents such as the starting currents of motors will not cause nuisance trip-outs.
- Schneider Electric solutions
  - Type G Compact \(2I_n \leq I_{\text{rm}} \leq 4I_n\)
  - Type B Multi 9 circuit-breaker

**Suggestion 2** (see Fig. F53)
- Install a RCD on the circuit. The device does not need to be highly-sensitive (HS) (several amps to a few tens of amps). Where socket-outlets are involved, the particular circuits must, in any case, be protected by HS (< 30 mA) RCDs; generally one RCD for a number of socket outlets on a common circuit.
- Schneider Electric solutions
  - RCD Multi 9 NG125: \(I_{\Delta n} = 1\) or \(3\) A
  - Vigicompact REH or REM: \(I_{\Delta n} = 3\) to \(30\) A
  - Type B Multi 9 circuit-breaker

**Suggestion 3**
Increase the size of the PE or PEN conductors and/or the phase conductors, to reduce the loop impedance.

**Suggestion 4**
Add supplementary equipotential conductors. This will have a similar effect to that of suggestion 3, i.e. a reduction in the earth-fault-loop resistance, while at the same time improving the existing touch-voltage protection measures. The effectiveness of this improvement may be checked by a resistance test between each exposed conductive part and the local main protective conductor.

For TN-C installations, bonding as shown in Figure F54 is not allowed, and suggestion 3 should be adopted.
7 Implementation of the IT system

The basic feature of the IT earthing system is that, in the event of a short-circuit to earth fault, the system can continue to operate without interruption. Such a fault is referred to as a “first fault”.

In this system, all exposed conductive parts of an installation are connected via PE conductors to an earth electrode at the installation, while the neutral point of the supply transformer is:

- Either isolated from earth
- Or connected to earth through a high resistance (commonly 1,000 ohms or more)

This means that the current through an earth fault will be measured in milli-amps, which will not cause serious damage at the fault position, or give rise to dangerous touch voltages, or present a fire hazard. The system may therefore be allowed to operate normally until it is convenient to isolate the faulty section for repair work. This enhances continuity of service.

In practice, the system earthing requires certain specific measures for its satisfactory exploitation:

- Permanent monitoring of the insulation with respect to earth, which must signal (audibly or visually) the occurrence of the first fault
- A device for limiting the voltage which the neutral point of the supply transformer can reach with respect to earth
- A “first-fault” location routine by an efficient maintenance staff. Fault location is greatly facilitated by automatic devices which are currently available
- Automatic high-speed tripping of appropriate circuit-breakers must take place in the event of a “second fault” occurring before the first fault is repaired. The second fault (by definition) is an earth fault affecting a different live conductor than that of the first fault (can be a phase or neutral conductor).

The second fault results in a short-circuit through the earth and/or through PE bonding conductors.

---

Fig. F56: Positions of essential functions in 3-phase 3-wire IT-earthed system

(1) On systems where the neutral is distributed, as shown in Figure F60.
7.2 Protection against indirect contact

First-fault condition
The earth-fault current which flows under a first-fault condition is measured in milliamps.
The fault voltage with respect to earth is the product of this current and the resistance of the installation earth electrode and PE conductor (from the faulted component to the electrode). This value of voltage is clearly harmless and could amount to several volts only in the worst case (1,000 Ω earthing resistor will pass 230 mA\(^{(1)}\) and a poor installation earth-electrode of 50 ohms, would give 11.5 V, for example).
An alarm is given by the permanent insulation monitoring device.

Principle of earth-fault monitoring
A generator of very low frequency a.c. current, or of d.c. current, (to reduce the effects of cable capacitance to negligible levels) applies a voltage between the neutral point of the supply transformer and earth. This voltage causes a small current to flow according to the insulation resistance to earth of the whole installation, plus that of any connected appliance.

Low-frequency instruments can be used on a.c. systems which generate transient d.c. components under fault conditions. Certain versions can distinguish between resistive and capacitive components of the leakage current.

Modern equipment allow the measurement of leakage-current evolution, so that prevention of a first fault can be achieved.

Examples of equipment

- Manual fault-location (see Fig. F57)
The generator may be fixed (example: XM100) or portable (example: GR10X permitting the checking of dead circuits) and the receiver, together with the magnetic clamp-type pick-up sensor, are portable.

![Fig. F57: Non-automatic (manual) fault location](image)

- Fixed automatic fault location (see Fig. F58 next page)
The monitoring relay XM100, together with the fixed detectors XD1 or XD12 (each connected to a toroidal CT embracing the conductors of the circuit concerned) provide a system of automatic fault location on a live installation.

Moreover, the level of insulation is indicated for each monitored circuit, and two levels are checked: the first level warns of unusually low insulation resistance so that preventive measures may be taken, while the second level indicates a fault condition and gives an alarm.

\(^{(1)}\) On a 230/400 V 3-phase system.
Automatic monitoring, logging, and fault location (see Fig. F59)
The Vigilohm System also allows access to a printer and/or a PC which provides a global review of the insulation level of an entire installation, and records the chronological evolution of the insulation level of each circuit.

The central monitor XM100, together with the localization detectors XD08 and XD16, associated with toroidal CTs from several circuits, as shown below in Figure F59, provide the means for this automatic exploitation.
7 Implementation of the IT system

Implementation of permanent insulation-monitoring (PIM) devices
- Connection
  The PIM device is normally connected between the neutral (or artificial neutral) point of the power-supply transformer and its earth electrode.
- Supply
  Power supply to the PIM device should be taken from a highly reliable source. In practice, this is generally directly from the installation being monitored, through overcurrent protective devices of suitable short-circuit current rating.
- Level settings
  Certain national standards recommend a first setting at 20% below the insulation level of the new installation. This value allows the detection of a reduction of the insulation quality, necessitating preventive maintenance measures in a situation of incipient failure.

The detection level for earth-fault alarm will be set at a much lower level.

By way of an example, the two levels might be:
- New installation insulation level: 100 kΩ
- Leakage current without danger: 500 mA (fire risk at > 500 mA)
- Indication levels set by the consumer:
  - Threshold for preventive maintenance: 0.8 x 100 = 80 kΩ
  - Threshold for short-circuit alarm: 500 Ω

Notes:
- Following a long period of shutdown, during which the whole, or part of the installation remains de-energized, humidity can reduce the general level of insulation resistance. This situation, which is mainly due to leakage current over the damp surface of healthy insulation, does not constitute a fault condition, and will improve rapidly as the normal temperature rise of current-carrying conductors reduces the surface humidity.
- The PIM device (XM) can measure separately the resistive and the capacitive current components of the leakage current to earth, thereby deriving the true insulation resistance from the total permanent leakage current.

The case of a second fault

A second earth fault on an IT system (unless occurring on the same conductor as the first fault) constitutes a phase-phase or phase-to-neutral fault, and whether occurring on the same circuit as the first fault, or on a different circuit, overcurrent protective devices (fuses or circuit-breakers) would normally operate an automatic fault clearance.

The settings of overcurrent tripping relays and the ratings of fuses are the basic parameters that decide the maximum practical length of circuit that can be satisfactorily protected, as discussed in Sub-clause 6.2.

Note: In normal circumstances, the fault current path is through common PE conductors, bonding all exposed conductive parts of an installation, and so the fault loop impedance is sufficiently low to ensure an adequate level of fault current. Where circuit lengths are unavoidably long, and especially if the appliances of a circuit are earthed separately (so that the fault current passes through two earth electrodes), reliable tripping on overcurrent may not be possible.

In this case, an RCD is recommended on each circuit of the installation.

Where an IT system is resistance earthed, however, care must be taken to ensure that the RCD is not too sensitive, or a first fault may cause an unwanted trip-out. Tripping of residual current devices which satisfy IEC standards may occur at values of 0.5 \(I_{\text{n}}\) to \(I_{\text{n}}\), where \(I_{\text{n}}\) is the nominal residual-current setting level.

Methods of determining levels of short-circuit current

A reasonably accurate assessment of short-circuit current levels must be carried out at the design stage of a project.

A rigorous analysis is not necessary, since current magnitudes only are important for the protective devices concerned (i.e. phase angles need not be determined) so that simplified conservatively approximate methods are normally used. Three practical methods are:
- The method of impedances, based on the vectorial summation of all the (positive-phase-sequence) impedances around a fault-current loop
- The method of composition, which is an approximate estimation of short-circuit current at the remote end of a loop, when the level of short-circuit current at the near end of the loop is known. Complex impedances are combined arithmetically in this method
- The conventional method, in which the minimum value of voltage at the origin of a faulty circuit is assumed to be 80% of the nominal circuit voltage, and tables are used based on this assumption, to give direct readings of circuit lengths.

Three methods of calculation are commonly used:
- The method of impedances, based on the trigonometric addition of the system resistances and inductive reactances
- The method of composition
- The conventional method, based on an assumed voltage drop and the use of prepared tables
The software Ecodial is based on the “method of impedance”

The maximum length of an IT earthed circuit is:
- For a 3-phase 3-wire scheme
  \[ L_{\text{max}} = \frac{0.8 \, U_o \, \sqrt{3} \, S_{\text{ph}}}{2 \, \rho_1 a (1 + m)} \]
- For a 3-phase 4-wire scheme
  \[ L_{\text{max}} = \frac{0.8 \, U_o \, S_1}{2 \, \rho_1 a (1 + m)} \]

These methods are reliable only for the cases in which wiring and cables which make up the fault-current loop are in close proximity (to each other) and are not separated by ferro-magnetic materials.

Methods of impedances
This method as described in Sub-clause 6.2, is identical for both the IT and TN systems of earthing.

Methods of composition
This method as described in Sub-clause 6.2, is identical for both the IT and TN systems of earthing.

Conventional method (see Fig. F60)
The principle is the same for an IT system as that described in Sub-clause 6.2 for a TN system: the calculation of maximum circuit lengths which should not be exceeded downstream of a circuit-breaker or fuses, to ensure protection by overcurrent devices. It is clearly impossible to check circuit lengths for every feasible combination of two concurrent faults.

All cases are covered, however, if the overcurrent trip setting is based on the assumption that a first fault occurs at the remote end of the circuit concerned, while the second fault occurs at the remote end of an identical circuit, as already mentioned in Sub-clause 3.4. This may result, in general, in one trip-out only occurring (on the circuit with the lower trip-setting level), thereby leaving the system in a first-fault situation, but with one faulty circuit switched out of service.

For the case of a 3-phase 3-wire installation the second fault can only cause a phase/phase short-circuit, so that the voltage to use in the formula for maximum circuit length is \( \sqrt{3} \, U_o \).

The maximum circuit length is given by:

\[ L_{\text{max}} = \frac{0.8 \, U_o \, \sqrt{3} \, S_{\text{ph}}}{2 \, \rho_1 a (1 + m)} \text{ metres} \]

For the case of a 3-phase 4-wire installation the lowest value of fault current will occur if one of the faults is on a neutral conductor. In this case, \( U_o \) is the value to use for computing the maximum cable length, and

\[ L_{\text{max}} = \frac{0.8 \, U_o \, S_1}{2 \, \rho_1 a (1 + m)} \text{ metres} \]

i.e. 50% only of the length permitted for a TN scheme (1)

---

Fig. F60: Calculation of \( L_{\text{max}} \) for an IT-earthed system, showing fault-current path for a double-fault condition

(1) Reminder: There is no length limit for earth-fault protection on a TT scheme, since protection is provided by RCDs of high sensitivity.
In the preceding formulae:
Lmax = longest circuit in metres
Uo = phase-to-neutral voltage (230 V on a 230/400 V system)
ρ = resistivity at normal operating temperature (22.5 x 10⁻³ ohms-mm²/m for copper, 36 x 10⁻³ ohms-mm²/m for aluminium)
Ia = overcurrent trip-setting level in amps, or Ia = current in amps required to clear the fuse in the specified time
m = Sph
SPE = cross-sectional area of PE conductor in mm²
S1 = S neutral if the circuit includes a neutral conductor
S1 = Sph if the circuit does not include a neutral conductor

### Tables

The following tables have been established according to the “conventional method” described above.

The tables give maximum circuit lengths, beyond which the ohmic resistance of the conductors will limit the magnitude of the short-circuit current to a level below that required to trip the circuit-breaker (or to blow the fuse) protecting the circuit, with sufficient rapidity to ensure safety against indirect contact. The tables take into account:

- The type of protection: circuit-breakers or fuses, operating-current settings
- Cross-sectional area of phase conductors and protective conductors
- Type of earthing scheme
- Correction factor: Figure F61 indicates the correction factor to apply to the lengths given in tables F44 to F47, when considering an IT system

### Example

A 3-phase 3-wire 230/400 V installation is IT-earthed.

One of its circuits is protected by a circuit-breaker rated at 63 A, and consists of an aluminium-cored cable with 50 mm² phase conductors. The 25 mm² PE conductor is also aluminium. What is the maximum length of circuit, below which protection of persons against indirect-contact hazards is assured by the instantaneous magnetic tripping relay of the circuit-breaker?

Figure F46 indicates 603 metres, to which must be applied a correction factor of 0.36 (m = 2 for aluminium cable).

The maximum length is therefore 217 metres.

### 7.3 High-sensitivity RCDs

According to IEC 60364-4-41, high sensitivity RCDs (≤ 30 mA) must be used for protection of socket outlets with rated current ≤ 20 A in all locations. The use of such RCDs is also recommended in the following cases:

- Socket-outlet circuits in wet locations at all current ratings
- Socket-outlet circuits in temporary installations
- Circuits supplying laundry rooms and swimming pools
- Supply circuits to work-sites, caravans, pleasure boats, and travelling fairs

See 2.2 and chapter P, al section 3

---

(1) The tables are those shown in Sub-clause 6.2 (Figures F45 to F48). However, the table of correction factors (Figure F61) which takes into account the ratio Sph/SPE, and of the type of circuit (3-ph 3-wire; 3-ph 4-wire; 1-ph 2-wire) as well as conductor material, is specific to the IT system, and differs from that for TN.
7 Implementation of the IT system

7.4 Protection in high fire-risk locations

Protection by a RCD of sensitivity \( \leq 500 \text{ mA} \) at the origin of the circuit supplying the fire-risk locations is mandatory in some countries (see Fig. F63). A preferred sensitivity of 300 mA may be adopted.

7.5 When the fault current-loop impedance is particularly high

When the earth-fault current is restricted due to an inevitably high fault-loop impedance, so that the overcurrent protection cannot be relied upon to trip the circuit within the prescribed time, the following possibilities should be considered:

**Suggestion 1** (see Fig. F64)
- Install a circuit-breaker which has an instantaneous magnetic tripping element with an operation level which is lower than the usual setting, for example: \( 2I_n \leq I_{rm} \leq 4I_n \)

This affords protection for persons on circuits which are abnormally long. It must be checked, however, that high transient currents such as the starting currents of motors will not cause nuisance trip-outs.

**Schneider Electric solutions**
- Type G Compact (\( 2I_m \leq I_{rm} \leq 4I_m \))
- Type B Multi 9 circuit-breaker

**Suggestion 2** (see Fig. F65)
Install a RCD on the circuit. The device does not need to be highly-sensitive (HS) (several amps to a few tens of amps). Where socket-outlets are involved, the particular circuits must, in any case, be protected by HS (\( \leq 30 \text{ mA} \)) RCDs; generally one RCD for a number of socket outlets on a common circuit.

**Schneider Electric solutions**
- RCD Multi 9 NG125 : \( I_{\Delta n} = 1 \text{ or } 3 \text{ A} \)
- Vigicompact REH or REM: \( I_{\Delta n} = 3 \text{ to } 30 \text{ A} \)

**Suggestion 3**
Increase the size of the PE conductors and/or the phase conductors, to reduce the loop impedance.

**Suggestion 4** (see Fig. F66)
Add supplementary equipotential conductors. This will have a similar effect to that of suggestion 3, i.e. a reduction in the earth-fault-loop resistance, while at the same time improving the existing touch-voltage protection measures. The effectiveness of this improvement may be checked by a resistance test between each exposed conductive part and the local main protective conductor.

8 Residual current devices (RCDs)

8.1 Description

Principle

The essential features are shown schematically in Figure F67 below.

A magnetic core encompasses all the current-carrying conductors of an electric circuit and the magnetic flux generated in the core will depend at every instant on the arithmetical sum of the currents; the currents passing in one direction being considered as positive (I1), while those passing in the opposite direction will be negative (I2).

In a normally healthy circuit I1 + I2 = 0 and there will be no flux in the magnetic core, and zero e.m.f. in its coil.

An earth-fault current I d will pass through the core to the fault, but will return to the source via the earth, or via protective conductors in a TN-earthed system.

The current balance in the conductors passing through the magnetic core therefore no longer exists, and the difference gives rise to a magnetic flux in the core.

The difference current is known as the “residual” current and the principle is referred to as the “residual current” principle.

The resultant alternating flux in the core induces an e.m.f. in its coil, so that a current I 3 flows in the tripping-device operating coil. If the residual current exceeds the value required to operate the tripping device either directly or via an electronic relay, then the associated circuit-breaker will trip.

---

8.2 Recommendations for RCDs implementation

Permanent earth leakage currents

Every LV installation has a permanent leakage current to earth, which is either due to:

- Unbalance(1) of the intrinsic capacitance between live conductors and earth for three-phase circuits or
- Capacitance between live conductors and earth for single-phase circuits

The larger the installation the greater its capacitance with consequently increased leakage current.

The capacitive current to earth is sometimes increased significantly by filtering capacitors associated with electronic equipment (automation, informatics and computer-based systems, etc.).

In the absence of more-precise data, permanent leakage current in a given installation can be estimated from the following values, measured at 230 V 50 Hz:

- Single-phase or three-phase circuit: 1.5 mA /100m
- Heating floor: 1 mA / kW
- Fax terminal: 1 mA

Earth-leakage currents which are not due to a fault, as well as transient overvoltages, can lead to unwanted tripping by RCDs. Some techniques have been developed to overcome these operational problems.

(1) On 3-phase systems the capacitive leakage current to earth would be zero if the conductors of all three phases had equal capacitance to earth, a condition that cannot be realized in practical installations.
F - Protection against electric shock

Since RCDs complying with IEC and many national standards may operate within the range 0.5 \( \Delta I_n \) - \( \Delta I_n \) for a nominal rating of \( \Delta I_n \), the leakage current downstream of a RCD must not exceed 0.5 \( \Delta I_n \).

The limitation of permanent leakage current to 0.25 \( \Delta I_n \), by sub-division of circuits, will, in practice, eliminate any unwanted tripping.

For very particular cases, such as the extension, or partial renovation of extended IT-earthed installations, the manufacturers must be consulted.

### Transient leakage currents

**Energization**

The initial energization of the capacitances mentioned above gives rise to high-frequency transient currents of very short duration, similar to that shown in Figure F68. The sudden occurrence of a first-fault on an IT-earthed system also causes transient earth-leakage currents at high frequency, due to the sudden rise of the two healthy phases to phase/phase voltage above earth.

**Common mode overvoltages**

Electrical power networks are subjected to overvoltages of various origins: atmospheric, or due to abrupt changes of system operating conditions (faults, fuse operation, switching, etc.). These sudden changes often cause large transient voltages and currents in system inductive and capacitive circuits, before a new stable state is reached. Records have established that, on LV systems, overvoltages remain generally below 6 kV, and that they can be adequately represented by the conventional 1.2/50 \( \mu \)s impulse wave (see Fig. F69).

These overvoltages give rise to transient currents represented by a current impulse wave of the conventional 8/20 \( \mu \)s form, having a peak value of several tens of amperes (see Fig. F70).

The transient currents flow to earth via the capacitances of the installation surge arresters or through an insulation failure.

**Immunity to transients**

Every RCD installed must have a minimum level of immunity to unwanted tripping in conformity with the requirements of Figure F71. RCDs type “S” or time-delay setting levels I or II (see Fig. F38) cover all transient leakage currents, including those of lightning arresters of a duration less than 40 ms.

The high-frequency (or unidirectional impulse) transient overvoltages and currents mentioned above, together with other electromagnetic disturbance sources (contactor coils, relays, dry contacts), electrostatic discharges, and radiated electromagnetic waves (radio, ignition systems, etc.) are part of the increasingly important field of EMC (electromagnetic compatibility). For further details the Technical publications nos. 120 and 149, by Schneider Electric, may be consulted.

---

### Disturbance Tests

---

Schneider Electric - Electrical installation guide 2007
In practice, the levels shown in Figure F71 are complied with in design and manufacturing specifications.

**Type “A Si” RCDs** avoid unwanted tripping in case of polluted network, lightning effect, high frequency currents, DC components, transient, low operating temperature (-25 °C).

**Immunity to Direct current components** (see Fig. F73)

Auxiliary d.c. supplies for control and indication of electrical and mechanical equipment are common, and certain appliances include rectifiers (diodes, triacs, thyristors).

In the event of an earth fault downstream of a rectifier, the fault current can include a d.c. component.

The risk depends on the level of insulation of the d.c. circuits in an appliance, and each case must be considered individually. Problems of this kind generally concern industrial applications.

The IEC classifies RCDs according to their ability to function correctly in the presence of d.c. components in the residual current.

- **Class AC**: Operates due to a.c. current only
- **Class A**: Operates if residual current consists of uni-directional pulses
- **Class B**: Operates on pure d.c.

**Note**: For general use Class AC RCDs are normally installed. Class A are available for specific requirements as a special variation of Class AC devices.

**Recommendations concerning the installation of RCDs with separate toroidal current transformers**

The detector of residual current is a closed magnetic circuit (usually circular) of very high magnetic permeability, on which is wound a coil of wire, the ensemble constituting a toroidal (or ring-type) current transformer.

Because of its high permeability, any small deviation from perfect symmetry of the conductors encompassed by the core, and the proximity of ferrous material (steel enclosure, chassis members, etc.) can affect the balance of magnetic forces sufficiently, at times of large load currents (motor-starting current, transformer energizing current surge, etc.) to cause unwanted tripping of the RCD.

Unless particular measures are taken, the ratio of operating current \( I_{\Delta n} \) to maximum phase current \( I_{ph} \) (max.) is generally less than 1/1,000.

This limit can be increased substantially (i.e. the response can be desensitized) by adopting the measures shown in Figure F74, and summarized in Figure F75.

<table>
<thead>
<tr>
<th>Measures</th>
<th>Diameter (mm)</th>
<th>Sensitivity diminution factor</th>
</tr>
</thead>
<tbody>
<tr>
<td>Careful centralizing of cables through the ring core</td>
<td></td>
<td>3</td>
</tr>
<tr>
<td>Oversizing of the ring core</td>
<td>( \phi 50 \to \phi 100 )</td>
<td>2</td>
</tr>
<tr>
<td></td>
<td>( \phi 80 \to \phi 200 )</td>
<td>2</td>
</tr>
<tr>
<td></td>
<td>( \phi 120 \to \phi 300 )</td>
<td>6</td>
</tr>
<tr>
<td>Use of a steel or soft-iron shielding sleeve</td>
<td></td>
<td>3</td>
</tr>
<tr>
<td>■ Of wall thickness 0.5 mm</td>
<td>( \phi 50 )</td>
<td>4</td>
</tr>
<tr>
<td>■ Of length 2 x inside diameter of ring core</td>
<td>( \phi 80 )</td>
<td>3</td>
</tr>
<tr>
<td>■ Completely surrounding the conductors and overlapping the circular core equally at both ends</td>
<td>( \phi 120 )</td>
<td>3</td>
</tr>
<tr>
<td>■ Completely surrounding the conductors and overlapping the circular core equally at both ends</td>
<td>( \phi 200 )</td>
<td>2</td>
</tr>
</tbody>
</table>

These measures can be combined. By carefully centralizing the cables in a ring core of 200 mm diameter, where a 50 mm core would be large enough, and using a sleeve, the ratio 1/1,000 could become 1/30,000.

**Fig. F74**: Three measures to reduce the ratio \( I_{\Delta n}/I_{ph} \) (max.)

**Fig. F75**: Means of reducing the ratio \( I_{\Delta n}/I_{ph} \) (max.)
B - Protection against electric shock

8 Residual current devices (RCDs)

Choice of characteristics of a residual-current circuit-breaker (RCCB - IEC 61008)

Rated current

The rated current of a RCCB is chosen according to the maximum sustained load current it will carry.

- If the RCCB is connected in series with, and downstream of a circuit-breaker, the rated current of both items will be the same, i.e. \( I_n = I_{n1}^{(1)} \) (see Fig. F76a).
- If the RCCB is located upstream of a group of circuits, protected by circuit-breakers, as shown in Figure F76b, then the RCCB rated current will be given by: \( I_n = k_u \times k_s \times (I_{n1} + I_{n2} + I_{n3} + I_{n4}) \)

Electrodynamic withstand requirements

Protection against short-circuits must be provided by an upstream SCPD (Short-Circuit Protective Device) but it is considered that where the RCCB is located in the same distribution box (complying with the appropriate standards) as the downstream circuit-breakers (or fuses), the short-circuit protection afforded by these (outgoing-circuit) SCPDs is an adequate alternative. Coordination between the RCCB and the SCPDs is necessary, and manufacturers generally provide tables associating RCCBs and circuit-breakers or fuses (see Fig. F77).
